In situ TEM observing structural transitions of MoS₂ upon sodium insertion and extraction†

Liqiang Zhang,^{‡ab} Yushu Tang,^{‡ab} Yuecun Wang,^{‡c} Yongli Duan,^a Degang Xie,^c Chunyang Wu,^d Lishan Cui,^{ab} Yongfeng Li,^{*a} Xiaohui Ning^{*c} and Zhiwei Shan^c

In this study, the sodiation and desodiation processes of MoS₂ were characterized by using an *in situ* TEM technique. The structural evolution of MoS₂ and its performance in a coin-type cell are recognized. Our findings provide a fundamental understanding of the reaction mechanism of MoS₂ as anode for Na ion batteries.

Recently, Na ion batteries (NIB) have been rapidly developed as an alternative to Li ion batteries (LIB) with an increasing number of experimental and theoretical studies.^{1–6} As we know, the element Na is located next to Li among the alkali metals in the periodic table, and displays similar chemical actives as Li but with a much cheaper price and more abundant storage in nature.^{7–9} Plenty of anode materials such as FeS₂, SnO₂, CuO and MoS₂ have been selected for NIBs, demonstrating good performances in experiments.^{10–14} Among these promising anode materials, the layer structured material MoS₂ can accommodate guest ions intrinsically with a minimum structural distortion, which provides a good channel for the ions transportation. The weak interaction bonds between MoS₂ layers and larger interlayer spacing enables the Na ions insert and extract smoothly during cycling but without obviously volume expansion.¹⁴ Previous studies have proposed that exfoliated MoS₂ nanosheet can operate stably in NIBs.^{13,15,16} The crystalline structure evolution of MoS₂ upon sodiation is closely related to its electronic properties, which plays a significant role

in determining the performance of the battery.¹⁷ However, limited researches have been conducted on *in situ* characterizing and analyzing this process.

Understanding the detailed microscopic mechanisms of the electrochemical reaction and material degradation is crucial for the designing of high performance MoS₂ anodes for NIB. Thus in this work, an *in situ* transmission electron microscopy (TEM) technique has been applied to investigate the structural and chemical evolution of MoS₂ during Na ions insertion and desorption, providing a fundamental studying of the electrochemical reaction mechanism of MoS₂ as anode for NIBs.

The *in situ* electrochemical tests and TEM imaging were carried out by an *in situ* electric testing system, Hysitron P195 H1H, inside the Hitachi H9500 TEM operated at 300 keV. In order to confirm the negligible effects of electron beam on electrochemical reactions, both beam-on and blank experiments were performed, respectively. The MoS₂ sample is prepared by means of supercritical CO₂ fluid shear, and the preparation progress is discussed in the ESI (Fig. S1†). A coin cell was also assembled to characterize the electrochemical performance of MoS₂ NIB. The electrochemical Na-storage properties of the MoS₂ were evaluated by galvanostatic cycling using CR2025-type coin cells. The cells were charged and discharged at various current densities between 0.005 and 3.0 V vs. Na/Na⁺ on a Neware battery tester (Shenzhen, China). The specific capacity of MoS₂/G was calculated based on the total weight of MoS₂ and graphite. Cyclic voltammetry (CV) scanning was carried out on an Arbin BT2000 system between 0.005 and 3.0 V vs. Na/Na⁺ at various scan rates using three-electrode beaker cells with Na foil as both the counter and reference electrodes. All of the electrochemical measurements were carried out at room temperature.

Here we examined the complete Na intercalation process in lamellar MoS₂ nanosheets *via* an *in situ* TEM approach to directly capture the dynamic changes. Fig. 1(a) shows a schematic illustration of the setup of MoS₂ NIBs. Metal Na serving as counter electrode is scratched by electrochemically shaped tungsten (W) tips. (e) A HRTEM image of a MoS₂ nanosheet and the corresponding EDP shown in the upper inset.

hydroxide (Na₂O and NaOH) on the Na metal serve as a solid electrolyte. The lamellar MoS₂ electrodes were prepared by sticking a very thin sheet from the prepared MoS₂ nanosheet (Fig. 1(b)) to another W rod with conductive silver epoxy, these two electrodes are incorporated into the TEM specimen holder. Fig. 1(c) shows the TEM image for a MoS₂ nanosheet, which is thin enough to count its number of layer as shown in the HRTEM image (Fig. 1(d)). Fig. 1(e) shows the superstructure of MoS₂ nanosheet, and its corresponding electron diffraction pattern (EDP) is shown in the inset, which can be well indexed to the (010) and (100) planes of 2H-MoS₂ along the [001] zone axis ($a = 3.16$, JCPDF no. 06-0097).

Once the Na₂O-covered Na electrode driven by a piezoceramic manipulator was contacted to the MoS₂ nanosheet, a constant voltage was immediately applied on the sample to sodiate the MoS₂. The structural evolution of MoS₂ upon sodiation was recorded in Fig. 2(a–c), it shows that Na ions insert immediately into the space between the MoS₂ layers once the MoS₂ nanosheet attaches the metal Na electrode. When the reaction front is generated, it propagates extremely fast and sweeps across the MoS₂ sheet within a few seconds, as marked by the red arrows. The sodiated MoS₂ nanosheet can be separated into two segments

Fig. 2 *In situ* electrochemical reaction of lamellar MoS₂ nanosheets with Na. (a–c) A series of TEM images showing microstructural evolutions for a MoS₂ nanosheet during the first sodiation process. (d–f) *In situ* EDPs showing that MoS₂ was converted to Na₂S.

with different contrasts by the reaction fronts, corresponding to the pristine MoS₂ nanosheet on the right and the sodiated amorphous product on the left side, respectively. A real-time movie characterizing the first sodiation process is shown in ESI (movie S1†). The EDPs of the MoS₂ taken prior to, upon, and after the sodiation reaction are shown in Fig. 2(d–f), respectively. The pristine MoS₂ demonstrates obvious sharp Bragg spots in this EDP (Fig. 2(d)), indicating the single crystal structure of MoS₂. As the inserting of Na ions, those sharp spots become indistinct. Meanwhile some dim ones are generated between every two bright spots (forming a 2 × 2 superstructure). A typical structural transformation of MoS₂ from 2H to 1T is supposed to take place in this process (Fig. S2†), which is also observed upon the lithiation of MoS₂.¹⁸ Meanwhile, some dim diffraction circles appear in Fig. 2(e) and the small circle near the center can be indexed to the (111) plane of Na₂S (JCPDF no. 03-0933) as marked by the yellow semicircle. It suggests that on this stage, a little amount of Na₂S has been generated in some part of the sodiated MoS₂ nanosheet. The sodiated structure has evolved into a 2 × 2 superstructure of Na_xMoS₂ mixing with a little amount of amorphous Na₂S. As the sodiation reaction goes on, more Na ions inserted into the MoS₂ nanosheets and the diffraction pattern changed from spots (Fig. 2(e)) into some brighter circles (Fig. 2(f)), which can be well indexed to the (111), (220) and (400) planes of Na₂S (JCPDF no. 03-0933). This change indicates that an amorphous Na₂S structure in the fully sodiated phase is formed, without any superstructure remaining, which means that the intercalation of more Na ions leads to lattice distortion of MoS₂ and formation of Na₂S. More Na ions insertion improve the bond formation between the Na and S atoms, which helps the formation of more Na₂S.¹⁷ The reaction can be formulated as following equations:¹⁸

Noted that there is no diffraction pattern of Mo in Fig. 2(f). It is believed that the metallic Mo is well dispersed at the nano-scale level.¹⁷

Fig. 3 shows the microstructure evolutions of MoS₂ for the first sodiation and desodiation process. In Fig. 3(a–d), a nanoscale Na particle is gradually disappeared, indicating that the Na ions are inserting into the MoS₂ nanosheets. With a longer sodiation time, the lamellar MoS₂ becomes darker and darker as more Na ions are inserted. In Fig. 3(e–h), an obvious Na particle is generated on MoS₂ upon the desodiation and grows bigger within a few seconds, marked by the yellow arrows, indicating that Na ions are escaped from the sodiated MoS₂ rapidly. It is noted that Na can be easily squeezed out from the edge of the MoS₂ layers (as shown in ESI movie S2†) indicating that Na prefers to migrate along the edge of the MoS₂ nanosheets and the inserted Na ions could migrate smoothly between the MoS₂ layers. The *in situ* TEM patterns show that the lamellar structure of MoS₂ is stable during the sodiation and desodiation process without a significant volume expansion, and it confirms that MoS₂ nanosheet is an ideal anode material for the energy storage. Galvanostatic discharge–charge cycling is performed to directly measure the capacity of the MoS₂ electrode during sodiation and desodiation in a coin-type cell. The galvanostatic discharge–charge cycling is performed in a coin cell to directly measure the capacity of the MoS₂ electrode at a constant current rate of 200 mA g^{−1}. The cycling performance of the MoS₂ nanosheets is shown in Fig. S3.† The initial discharge and charge capacity is 175 and 167 mA h g^{−1} respectively. These capacities decrease gradually with the repeated cycling. This electrode shows stable cycling behavior for extended cycling period up to 50 cycles. Fig. S4† shows the cyclic voltammograms of the MoS₂ electrode at a scan rate of 0.2 mV s^{−1}. In the first discharging process, there exists two reduction peaks at 0.57 and 0.71 V in the potential range of 0.01–3 V. In the following charging process, four oxidation peaks appear at 1.33, 1.78, 2.28, and 2.52 V, indicating that MoS₂ undergoes multiphase conversions during cycling. The redox peaks decrease gradually during cycling corresponding to a slow degradation of charge–discharge capacities.¹⁹ The above results indicate that MoS₂ anodes are ideal anode materials in practical NIBs. The MoS₂ nanosheets display no obvious changes in morphology during cycling, so they have a great potential to achieve long cycling lifetimes and good reversibility.

Fig. 3 Morphology evolutions of the MoS₂ nanosheet undergoing sodiation (a–d) and desodiation (e–h).

In conclusion, the detailed structure transformation of MoS₂ upon sodiation and desodiation processes have been characterized by using *in situ* TEM technique in this study. Upon the continuous sodiation of MoS₂, the pristine 2H-MoS₂ was first transformed to 1T-NaMoS₂ and finally converted into Na₂S phase. Meanwhile, the detailed microstructure evolution regarding the cycling process of MoS₂ nanosheets was also studied. The MoS₂ nanosheets assembled in a coin cell demonstrates a steady performance, indicating its layered structure provides an ideal channel for the Na ions migration in practical NIBs. These results provide important insights into understanding the mechanisms of structure evolution corresponding to the electrochemical property of MoS₂ during cycling.
